The prevalence of overweight and obesity among children has been increasing rapidly worldwide.1 In the United States, the age-adjusted prevalence of obesity based on the 95th percentile of body mass index nearly doubled from 1976–1980 to 1988–1994 for children in the 6 to 11 years and the 12 to 17 years age groups.2,3,4 This trend has continued since 1994. Recent data have shown that prevalence of overweight among children (6–11 years old) and adolescents (12–19 years old) was 13% and 14%, respectively, in 1999.5

Obesity in children and adolescents has been associated with several important chronic diseases such as diabetes, asthma, sleep apnea, and gallbladder disease.6,7 Several studies have documented that prevalence of type 2 diabetes mellitus is increasing among children and adolescents, and obesity may be a major contributor to the increase.8–11 However, neither trends in the prevalence of diseases associated with obesity in youths nor their impact on health care costs have previously been examined. This study explores the trends of disease and economic burden of obesity in youths from 1979 to 1999 with use of a nationally representative population sample of hospital discharges, the National Hospital Discharge Survey (NHDS).

The term overweight is used to describe children and adolescents whose body mass index is ≥95th percentile for youths of the same age and gender. The NHDS, however, lists obesity as a principal or a secondary diagnosis. Therefore, we will use the term obesity in this manuscript, although the use of the term reflects the provider’s judgment and likely underestimates the true prevalence of overweight-associated conditions and costs.

METHODS

Data Source

We used a multiyear data file of the NHDS, 1979–1999, conducted by the National Center for Health Statistics. This survey collects data from inpatient records acquired from a national sample of hospitals. The NHDS records annual discharges from noninstitutional hospitals, exclusive of federal, military, Veterans’ Administration hospitals, and hospital units of institutions, such as prison hospitals, located in the 50 States and the District of Columbia. Only short-stay hospitals (those with an average length of stay for all patients of <30 days), general (medical or surgical) hospitals, and children’s hospitals are included in the survey. Because persons with multiple discharges during the year may be sampled more than once, and no personal identifiers were available, discharges rather than persons were used for this study.

The survey design, sampling, and estimation procedures were planned to produce calendar-year estimates of inpatient stays. A detailed description of the sample design of the survey is provided elsewhere.12 In the survey, the medical information manually recorded on the sampled patients’ abstract was coded by National Center for Health Statistics staff who used the International Classification of Diseases, Ninth Revision, Clinical Modification (ICD-9-CM). A maximum of 7 diagnostic codes was assigned for each abstract sampled. The diagnostic code listed first was used as the principal diagnosis, and subsequent diagnostic codes (second through seventh) were used as secondary diagnoses.

Abbreviations. NHDS, National Hospital Discharge Survey; ICD-9, International Classification of Diseases, Ninth Revision.
The survey also provided demographic information, such as age, sex, and race. Data for race were missing for a total of about 13% of all discharges from all years, and no attempt was made to impute those missing values. In addition, because most obesity-related diseases occurred with a relatively low prevalence, we did not include race or other demographic variables in our analyses.

Analyses

We analyzed the hospital discharges from 1979 to 1999 of children and adolescents 6 to 17 years of age. We selected diabetes (ICD-9 250), obesity (ICD-9 278), sleep apnea (ICD-9 780.5, 786.09, and 789.03–789.07 for the year 1999 because of code changes), and gallbladder disease (ICD-9 574 and 575) for the analyses of trends. Because type 1 and type 2 diabetes cannot be reliably differentiated in our analyses, we considered only the hospitalizations in which diabetes and obesity were both listed as diagnoses as the criteria for type 2 diabetes when we analyzed hospital costs. Sleep apnea included sleep disturbances and other symptoms involving the respiratory system, and other chest symptoms such as apnea, shortness of breath, and wheezing. Gallbladder disease included cholelithiasis and cholecystitis. To examine the trend of the frequency of these diseases over the study period, we used the total number of discharges, including principal and secondary diagnoses during a year, and then pooled discharges from 3 consecutive years for additional analyses.

To quantify the health burden of these obesity-associated diseases over time, we estimated the number of discharges in the earliest 3-year (1979–1981) and the most recent 3-year (1997–1999) periods by principal and secondary diagnoses, separately. To understand better the obesity-associated health burden, we examined the other frequent principal diagnoses for discharges where obesity was listed as a secondary diagnosis.

On the basis of the health burden, we derived annual hospital cost by multiplying the total number of hospital stays (days of care) by the average hospital cost per day. We used an average cost per day of $249 for the community hospitals as the estimate of patient direct costs for hospital treatment during the period of 1979–1981. The average cost per day during 1997–1999 was $1066. For comparison purposes, we derived the hospital costs using year 2001 constant US dollars. We used a 5% inflation rate for this purpose. In 2001 constant dollars, the average cost per day was $694 for 1979–1981 and $1234 for 1997–1999. Because of the potential for double counting and uncertainty about the linkage between obesity and obesity-associated diseases, we included only the discharges with a diagnosis of obesity for the estimate of economic burden.

Because the NHDS used a stratified, multistage probability design, for data analysis we used SUDAAN (Research Triangle Park, NC), a statistical software package to take the complex sample design effects into account.

RESULTS

The percentage of hospital discharges of youths increased for all obesity-associated diseases over the period of 1979–1999 (Fig 1). The percentage of diabetes diagnoses increased from below 1.5% in 1979 to nearly 2.5% in 1999. The percentage of obesity discharges increased from below 0.5% to nearly 1.2%, and the increase was consistent and rapid after 1995. The frequency of sleep apnea and gallbladder disease also increased over the years.

The pattern of increase was more apparent and consistent when we pooled the discharges over 3 consecutive years (Table 1). From the 1979–1981 to the 1997–1999 period, the prevalence of diabetes increased from 1.43% to 2.36%, obesity from 0.36% to 1.07%, sleep apnea from 0.14% to 0.75%, and gallbladder disease from 0.18% to 0.59%. The trends were similar in children 6 to 11 years old and adolescents 12 to 17 years old, although the prevalence was higher in adolescents than in children for all diseases except sleep apnea (Fig 2A-D).

Table 2 presents the number of national hospital discharges extrapolated from the NHDS by sample weight for the 4 diseases during the earliest 3-year (1979–1981) and the most recent 3-year (1997–1999) study period. Most discharges with a diagnosis of diabetes listed it as a principal diagnosis (83% during 1979–1981 and 75% during 1997–1999). Over 70% of discharges with a gallbladder disease diagnosis listed it as a principal diagnosis. Only 4% of discharges with an obesity diagnosis listed it as a principal diagnosis during 1997–1999, and in that same period only 4% of discharges with a sleep apnea diagnosis listed it as a principal diagnosis. From 1979–1981 to 1997–1999, the total number of discharges increased by 55% for obesity, 175% for sleep apnea, and 74% for gallbladder disease.

During 1997–1999, the most frequent principal diagnoses when obesity was listed as a secondary diagnosis were asthma, disturbance of conduct such as unsocialized conduct and depressive disorders, and diabetes (Table 3). The frequency of disturbance of conduct in the earliest period (1979–1981) was very low. The rate of asthma as an obesity-associated comorbidity increased from 5.9% in 1979–1981 to 8.1% in 1997–1999. Outcome of delivery was a common principal diagnosis in 1997–1999 (4.6% vs 1.3% in 1979–1981). This diagnosis applied to girls 15 to 17 years of age with a single liveborn.

For both principal and secondary diagnosis of obesity, the length of stays were longer in 1997–1999 (13.46 days and 6.76 days, respectively) than in 1979–1981 (6.35 days and 5.01 days, respectively; Table 4). The total days of care associated with obesity increased from about 152 000 days in 1979–1981 to about 310 000 days in 1997–1999. In 1997–1999, the length of stay was 7.0 days for discharges with an obesity diagnosis and 4.4 days for overall discharges (Fig 3). The length of stay for obesity-associated discharges increased from 5.32 days in 1979–1981 to 7 days in 1997–1999, and it slightly decreased for the overall discharges.

Based on hospital utilization and average hospital cost per day, the annual hospital cost of $12.6 million during 1979–1981 increased to $110 million during 1997–1999 (Table 4). A major proportion of the cost was for discharges that listed obesity as a secondary diagnosis. After adjusting for inflation, in 2001 con-

constant dollars, annual hospital costs were about $35 million (0.43% of total hospital costs) during 1979–1981 and increased more than threefold to about $127 million (1.70% of total hospital costs) during 1997–1999.

DISCUSSION

The increase in the percentage of discharges with obesity-associated diseases may reflect the medical consequences of the obesity epidemic. Although the numbers of percentage are small, the increases are substantial, especially for obesity (197% increase), sleep apnea (436%), and gallbladder disease (228%). These data may suggest that the increasing prevalence of obesity in children and adolescents has led to increased hospital stays related to obesity-associated diseases. The increasing proportion of hospital discharges with obesity-associated diseases in the last 20 years may also reflect the impact of increasing severity of obesity. The higher proportion of hospital discharges of obesity-associated diseases in adolescents than in children for all of the diseases except sleep apnea may suggest further that obesity complications increase with age.

In the NHDS data reviewed for this study, obesity was usually listed as a secondary diagnosis. One potential explanation for this finding is that obesity is not generally a reimbursable diagnosis or medical health benefit. Health care payers may not reimburse for hospitalizations for obesity, even when obesity is the disease that causes diabetes, sleep apnea, or gallbladder disease. Therefore, doctors may not list obesity as a principal or even a secondary diagnosis. Lack of reimbursement may delay the treatment of obesity and lead to lost opportunities to prevent obesity-associated diseases. Reluctance to list obesity as a diagnosis may also make our estimates of disease burdens conservative.

The frequency with which other diseases have obesity listed as a secondary diagnosis suggests that obesity may lead to many other medical conditions. Asthma and some mental disorders have been linked to obesity. The frequencies with which obesity was listed as a secondary diagnosis for asthma and for several mental disorders increased from 1979–1981 to 1997–1999. Especially for mental disorders, no discharges listed obesity as a co-morbidity during 1979–1981, but by 1997–1999, obesity had become a common co-morbidity. For asthma, the frequency of discharges associated with obesity increased nearly 40%. Outcome of delivery was another common discharge that listed obesity as a co-morbidity during 1997–1999. The diagnosis frequency increased from 1.3% in 1979–1981 to 4.6% in 1997–1999. All of the patients in this category were girls 15 to 17 years of age with single liveborn. This increase may reflect the contribution of obesity to pregnancy complications and adverse pregnancy outcomes, such as cesarean delivery and pregnancy-induced hypertension.

The length of stay for discharges associated with obesity was longer than that for overall discharges. Discharges with a principal or secondary diagnosis of obesity yielded more days of hospital stay in recent years (1997–1999) than in earlier years (1979–1981), whereas the days of hospital stay decreased slightly for the overall discharges. When obesity was listed as a principal diagnosis, the average length of stay was twice that of discharges listing obesity as a secondary diagnosis (13.5 days vs 6.8 days). These data may reflect the time needed to treat obesity or to implement dietary or exercise strategies, or the time necessary to implement changes within families. The increased length of stay may also suggest that obesity treatment has become more complicated in recent years. For example, because of the increasing...
severity of obesity, more obese individuals may require gastric surgery.

The hospital costs associated with obesity may have risen to more than $127 million per year (in 2001 constant dollars) in recent years. These costs represent more than a threefold increase. As a percentage of costs for overall hospital discharges, obesity-associated costs increased from 0.43% in 1979–1981 to 1.7% in 1997–1999. The disparity between the changes in costs and the changes in prevalence of obesity may reflect the disproportionate increase in severe obesity from the 1970s to the 1990s.

This study had several limitations. First, the discharge frequency cannot be used to assess disease prevalence because a person with multiple discharges during a year may be sampled more than once. Second, physicians’ awareness of obesity or willingness to list obesity as a diagnosis may change over time. We did not consider this effect in analyzing discharge frequency because of lack of information. Third, only 4 obesity-associated diseases were examined for the trend analysis of diseases, and type 1 and type 2 diabetes were not differentiated, although we included only discharges that listed both obesity and diabetes for the analysis of economic costs. Fourth, we used only discharges with an obesity diagnosis to estimate the economic burden of obesity. Therefore, our estimates are probably conservative because many persons with obesity-associated diagnoses may not have a severe enough weight problem for obesity to be listed, or doctors may not have listed obesity as a diagnosis for reimbursement.

reasons. Finally, we analyzed hospital costs only. Other costs—costs for physician visits, medication, and indirect costs such as the effect of obesity on future earnings—are considerable. Inclusion of these costs would further increase the economic burden.

Several strengths of this study should also be noted. First, because this study used large, nationally representative samples collected over the past 20 years, we were able to examine trends and produce national estimates of hospital use and the economic burden of obesity. Although the proportion of obesity-associated discharges was low, the trend of the proportion and its economic costs are accelerating. Second, because principal and secondary diagnoses were available, we were able to examine other major comorbidities associated with obesity. Finally, although our estimates of diseases and economic costs associated with obesity are likely to be conservative in absolute values, the data from this 20-year period portray a disturbing increase of hospital diagnoses of obesity-associated diseases and in health care costs.

CONCLUSION

The increasing frequency of hospital discharges of obesity-associated diagnoses suggests a rising disease burden associated with obesity among children and adolescents. If the prevalence of obesity continues to grow, the disease burden will surely increase further. As overweight children become overweight adults, the diseases associated with obesity and health care costs are likely to increase even more. Because disproportionate weight gains have occurred among heavier children, the rate of obesity-associated diseases will rise even faster if the expanding prevalence of obesity continues. Clearly, both primary and secondary prevention of childhood obesity are required to address this epidemic.
